oxytocin | social adaptation | confidence | belief updating | optimism

Hadapting to the dynamic environment requires learning from feedback to accordingly update beliefs, change decisions, and guide future behaviors (1, 2). The hypothalamic peptide oxytocin (OT) is an evolutionarily ancient neuropeptide implicated in sociality and well-being (3, 4) and has been recently proposed as an important molecular substrate for social adaptation (5). The social adaptation model (5) posits that a fundamental function of OT is to promote adaptation to the social environment, by modifying cognitive processes and emotional responses and adjusting beThe effects of OT have been recognized to be modulated by personal milieu (5, 33). IN-OT produced stronger effects on less socially adapted individuals, such as those with high trait anxiety (34), impaired emotion regulation (35), or low emotional sensitivity (36). Because optimism has been implicated in anxiety and depression (26, 27, 37, 38), we further examined whether the effects of IN-OT on optimistic belief updating were moderated by individuals' depression and anxiety traits. Given the finding of stronger effects of IN-OT on less socially adapted individuals (34–36), we hypothesized that IN-OT would produce stronger effects on belief updating in individuals with high (relative to low) depression and anxiety traits. These hypotheses were tested in study 1 (as a discovery sample) and study 2 (as a replication sample) by asking participants to complete a two-stage belief updating task 40 min after OT or PL administration.

It has been revealed that an overt judgment (first-order estimation) is usually followed by a second-order judgment (e.g., confidence judgment; ref. 39). These two consecutive processes intertwine with each other and share neural underpinnings to guide decisionmaking (39, 40). Optimistic belief updating is often observed in situations incorporating uncertainty (21, 41), and low confidence is more likely to be associated with subsequent decision changes (40). Thus, we further investigated OT effects on participants' confidence in their first-order estimates in an independent study 3 (*SI Appendix*, Fig. S1B). Moreover, since alongside sensitivity to perceptions of internal processes (e.g., perceived confidence in estimation), sensitivity to information received externally (e.g., feedback) can facilitate better decisionmaking (42), we also assessed whether IN-OT would influence the degree to which participants accepted feedback (as external information). who scored high (vs. low) in each trait measure updated their estimates upon undesirable feedback to a greater degree (BDI: B =1.957, t(193) = 3.395, P = 0.001; DAS: B = 1.637, t(193) = 3.011, P =0.003; TA: B = 3.053, t(193) = 5.297, P < 0.001). Interestingly, OT treatment normalized the hyperupdates toward undesirable feedback for less socially adapted individuals. Under OT, BU_{Undes} did not vary significantly with individuals' trait scores (P > 0.25).

Distinct OT Effects on Learning of Desirable and Undesirable Feedback. To examine OT effects on the dynamic learning processes of desirable and undesirable feedback, for each participant we calculated the learning rate [i.e., the strength of association between the estimation error (prediction error) and the subsequent updates, SI Appendix, SI Methods], which has been suggested as a computational principle that underlies the observed biased belief formation by pointing to estimation errors as a learning signal (45) and reflects the dynamic learning processes of prediction errors (46). The Treatment × Feedback ANOVA of collapsed data from studies 1-3 revealed a significant main effect of Feedback as participants learned to a greater degree from estimation errors in the desirable (than undesirable) trials [F(1,306) = 246.482, P <0.001]. Moreover, relative to PL, IN-OT enhanced the learning rate of desirable estimation errors [F(1,306) = 11.779, P = 0.001], but not of undesirable ones (P > 0.2; Fig. 3). A significant Treatment × Feedback interaction on learning rate confirmed that IN-OT selectively increased learning from prediction error in the desirable but not undesirable trials $[F(1,30\hat{6}) = 13.687, P < 0.001,$ Fig. 3]. The same pattern of OT effects on learning rate was observed in each study (SI Appendix, Table S1 and Fig. S6).

OT Effects on Acceptance of Feedback and Confidence Judgment. The procedure of study 3 was similar to those in the studies 1 and 2 except that participants were additionally asked to rate their

confidence in their first and second estimates, respectively, and their acceptance of the feedback. A 2 (Treatment: OT vs. PL) × 2 (Feedback: Desirable vs. Undesirable) ANOVA of feedback acceptance failed to show significant main effects of Treatment (P > 0.2) or Feedback (F < 1). However, there was a significant Treatment × Feedback interaction on feedback acceptance [F(1,112) = 4.697, P = 0.032; Fig. 4A], because IN-OT (relative to PL) increased participants' acceptance of desirable feedback [F(1,112) = 4.320, P = 0.040] but failed to influence the acceptance of undesirable feedback (P > 0.8).

Confidence updates (confidence judgment of second Estimate minus that of first Estimate, i.e., CU = C2 - C1) were also subjected to ANOVAs with Treatment as a between-subjects factor and Feedback as a within-subject factor. There was a significant main effect of Feedback [F(1,112) = 17.966, P < 0.001] as participants demonstrated increasef innfide15.85fifThc-361.3(ig)n359.7(ineir)-291.

first examined the relationship between the optimistic bias in belief updating (OB, defined as $BU_{Des} - BU_{Undes}$) and measures of confidence/acceptance. We found that OB was significantly correlated only with CU_{Des} (r = 0.328, P < 0.001). There was no evidence for reliable correlations between OB and CU_{Undes} (r = 0.110, P = 0.245) or between OB and acceptance of desirable (r = -0.026, P = 0.780) or undesirable feedback (r = -0.013, P =0.887). We then conducted a mediation analysis (SI Appendix, SI Methods) to estimate whether the OT impact on OB was mediated by the OT effect on confidence updating. The mediation analysis confirmed that the OT effect on OB was mediated by its effect on confidence updating upon desirable feedback (Sobel test: t = 2.36, P = 0.018; SI Appendix, Fig. 4C and Tables S12– S15). The stepwise regression excluding Treatment was no longer significant when putting together with CU_{Des} , B = 2.76, t(111) = 1.42, P = 0.157, compared with initial coefficient, B =4.67, t(112) = 2.46, P = 0.016, suggesting that the OT effect on CU_{Des} acted as a full mediator of the OT effect on OB. A bootstrap resampling analysis (SI Appendix, SI Methods) of the effect size indicated that this mediation effect was different from zero with 95% confidence (confidence intervals: 0.58-4.32).

Matched Mood and Trait Between OT and PL Groups. OT and PL groups did not differ in age, trait optimism, mood, anxiety, depression-related cognitive distortions or symptoms, self-reports of event characteristics (*SI Appendix*, Tables S2 and S16–S18). Moreover, neither participants' memory performance nor reaction times during first and second estimation differed significantly between OT and PL groups (*SI Appendix*, Tables S19 and S20), suggesting that the IN-OT effects on belief updating cannot be attributed to OT-induced changes in cognitive abilities (e.g., reaction times, memory performance on feedback).

Discussion

The updating of beliefs upon feedback and adjusting behavior accordingly are pivotal to successful adaptation in a changing environment. Optimistic updating has evolved as an adaptive mechanism for physical and mental health (1, 2, 26–28). Here, we showed evidence supporting an impact of OT on optimistic belief updating. Specifically, we demonstrated that IN-OT increased belief updating upon undesirable feedback. The distinct OT effects on belief updating were also evident on the learning rate, i.e., OT selectively facilitated participants' learning from desirable but not undesirable prediction error to update their belief. Our findings complemented previous findings on OT effects on the

processing of social signals (10–15) by uncovering the OT impact on dynamic cognitive processes during belief formation and updating. Our results suggest that OT is a key molecular substrate for optimistic belief updating and plays opposing functional roles in belief updating upon desirable versus undesirable feedback.

Our results indicated that IN-OT (vs. PL) did not influence estimation times and memory of feedback, suggesting that the OT effects on optimistic updating were not driven by a general OT effect on attention or cognitive abilities. These results were in line with previous findings that optimistic updating could not be interpreted purely on the basis of selective attention, cognitive, or mnemonic abilities in processing desirable and undesirable feedback (19, 20, 45), but relied on a learning process involving asymmetric information integration (20, 41). It has been proposed that the uncertainty in prior knowledge relative to that of new data determines how posterior beliefs are formed (47). The more ambiguous and open to interpretation information is, the stronger the optimistic updating appears to be (41). Consistent with this proposition, we showed that the OT effect on optimistic updating was mediated by the effect of OT on confidence updating upon desirable feedback, suggesting a potential mechanism underlying OT-facilitated optimistic updating. IN-OT might increase individuals' trust in information about others (i.e., an average person), thus adjusting their belief during the second estimation with more confidence, especially in the desirable condition.

The findings of OT studies have suggested several mechanisms underlying OT effects on social cognition (5, 33) that, however, would predict different OT effects on updating of desirable and undesirable feedback. For example, the social motivation hypothesis, which proposes that OT mainly increases intrinsic reward from social interaction (48), predicts that IN-OT would facilitate updating upon desirable feedback but produce little effect on updating upon undesirable feedback. The social salience hypothesis, which suggests that OT enhances sensitivity to and salience of social cues independently of valence (33, 49), predicts thatid thatmainD[(indence)-m7cma results may lie in the social focus of trait measures (54). The studies, showing stronger OT effects in well-adapted individuals, used social-oriented trait measurement, such as the attachment anxiety scale that measured the attachment bond between participants and their parents (53). However, the studies showing stronger OT effects in less socially adapted individuals mainly used self-centered measures, such as anxiety traits measured by State-Trait Anxiety Inventory (STAI-T) (34), sociocognitive skills (9), or emotional sensitivity/regulation (35, 36). Similarly, we showed stronger OT effects in individuals with less socially adapted traits as measured by self-centered measures such as STAI-T, DAS (one's own maladaptive thinking patterns), and BDI (depressive symptoms). Taken together, the social-oriented and self-centered traits may interact with OT effects on cognition and behavior in different fashions.

Interestingly, we found a significant Treatment × Trait interaction on undesirable but not desirable belief updating. The OT effect on desirable updating was not modulated by anxiety or depressive traits, suggesting a general OT-increased desirable updating across individuals. Belief updating upon desirable feedback did not vary as a function of individuals' trait scores under PL, thus left no opportunity for IN-OT to normalize "abnormal" belief updating upon desirable feedback. Alternatively, a large variation (especially in the severe end) in trait measures may be required to reveal significant relationships between individuals' traits and belief updating upon desirable feedback (20). However, the current study recruited only healthy participants with a small variation in each trait scale (SI Appendix, Table S8). These possible accounts can be addressed in future research by examining the Treatment × Trait interactions in samples with a large variation in trait scores or in clinical populations. Whereas optimistic updating is adaptive for mental health, excessive optimism, especially ignoring undesirable information, can be maladaptive (1, 2, 55) and makes people less likely to take precautionary actions (56). Given that well-adapted individuals already show strong discounting of undesirable feedback under PL, reducing updating upon undesirable feedback could be hazardous for this cohort. Thus, the finding that OT did not reduce belief updating of undesirable feedback in well-adapted individuals may also reflect an adaptive mechanism for this cohort.

Our results were consistent with previous findings of distinct OT effects on positive and negative social-affective processes (5). IN-OT facilitated responses to positive social cues, increased positive social memory, and promoted positive value transmission to social interactions (5, 15, 33). Our findings suggested that OTinduced belief updates were biased toward positive information. Thus, OT may make positive information easier to be accessed and incorporated, so as to enhance recognition and memory of social cues and facilitate approach to positive signals. By contrast, IN-OT led to ignorance of undesirable feedback and, thus, may weaken the influence of undesirable information on subsequent decisionmaking and behavior. Consistently, previous studies showed that OT reduced recognition of and affective responses to negative signals, and failed to change behavior after the receipt of negative information (i.e., social betrayal; ref. 17). Animal studies also reported that OT abolished the impact of negative outcomes (such as traumatic events and aversive conditioning) on subsequent behaviors in rats and mice (57, 58). Our findings suggest a cognitive mechanism underlying such valence-specific OT effects: the facilitation of learning from positive information for subsequent updates and the reduction of learning from negative information.

Research has suggested the engagement of dopamine in optimistic updating (59). Administration of dihydroxy-L-phenylalanine that enhanced dopaminergic function facilitated optimism by impairing updating upon undesirable feedback (59). Although both the oxytocinergic and dopaminergic systems were involved in optimism, the cognitive route each system took to mediate except for the neuropeptide) was self-administrated by nasal spray under experimenter supervision. Finally, participants completed the mood measurement again.

The Belief Update Task. In studies 1 and 2, participants completed two sessions of life event estimation. Participants were first presented with 40 different adverse life events (SI Appendix, SI Methods) and estimated their likelihood (0–99%) of experiencing each event on a self-paced basis (first Estimate). Participants were then presented with the probability of each event occurring to an average person in a similar environment (Feedback). Five minutes after the first session, participants were invited to complete a second estimation session, in which participants were presented with these 40 events in a random order and estimated the likelihood of each event again (second Estimate). The number of desirable and undesirable trials was reported in SI Appendix, Table S21. After the second session, participants were given a

surprise memory test for the presented feedback. The belief update task in study 3 was similar to that in studies 1 and 2, except that, for each event, participants additionally made judgment of (i(ask.)Tfe209TJ0T6.91735c01463910TT(ea324

Supporting Methods

Pilot study to determine feedback for main experiments

The pilot study recruited 40 participants (15 males, mean age = 23.0 year, SD = 3.7). Participants were asked to estimate the probability (from 0 to 99%) of 100 different adverse life events that may happen to an average individual living in a similar socio-cultural environment. Eighty events were selected from the stimulus list of the previous study¹ and 20 additional events were complemented in the current study. Since all participants in the current study were college students, we asked participants to estimate the likelihood of these events occurring to an average Chinese college student. We also asked participants to identify those among the 100 life events that: 1) they had never heard of or did not understand; and 2) they were experiencing, or had experienced. An item was excluded if more than 5% of the participants had never heard of it, or did not understand it, or if more than 70% of the participants had experienced or were experiencing it. Forty-four adverse life events (e.g., "cancer", "obesity", "unemployed", "depression", "divorce" etc.) were randomly selected from the current stimulus set. Four adverse life events were used for practice and 40 adverse life events were used in the main experiments. The mean probability rating score of each event occurring to an average person obtained in this study was then used as social feedback in the main experiments.

Questionnaire measurement

On arrival in a testing room, all participants in the 3 studies first completed the Positive and Negative Affect Scale (PANAS²) and the Life Orientation Test Revised scale (LOT-R³) to measure their mood and optimistic trait. PANAS was administered again after the experiment to monitor their mood change. In Studies 2 and 3, participants also completed the Beck Depression Inventory (BDI⁴), the Dysfunctional Attitude Scale (DAS⁵) and the State Trait Anxiety Inventory (STAI⁶) before IN-OT/PL. The BDI, a 21-item multiple-choice inventory, was employed to measure depressive symptoms. Participants' cognitive distortions were measured using the 40-item DAS, which was designed to identify and measure cognitive distortions related to depression. Lower scores on DAS represent more adaptive beliefs and fewer cognitive distortions. Participant's trait and state anxiety was measured using the STAI, which contains 20 items for assessing trait anxiety and 20 for state anxiety. All items were rated on a 4-point scale, with higher scores indicating greater anxiety. After the experiment, PANAS was administered again to monitor mood change.

Data analysis

Hierarchical regression analyses. We performed hierarchical regression analyses to assess whether individual differences in depression or anxiety traits moderated OT effects on belief update (BU). We normalized the independent variable (Treatment, coded as a dichotomous dummy variable in which 0 represented PL and 1 represented IN-OT) and the covariate variable (normalized BDI, DAS and TA scores, respectively). Three moderated hierarchical regression models were built, respectively with BDI, DAS, or TA scores as moderator. For each model, normalized Treatment, BDI, DAS, or TA scores, and their interaction were sequentially entered as predictor variables. These analyses were conducted separately with BU_{Des} and BU_{Undes} as dependent variable. The significant Treatment x Trait interaction was followed up with tests of simple slopes, which assessed the magnitude of different effects that contributed to an interaction.

Learning rate. Learning rate was calculated as the strength of the association between the estimation error (prediction error, PE) and the subsequent updates (update) for desirable and undesirable trials, respectively. The learning rate has been suggested as a computational principle that underlies the observed biased belief formation by pointing to estimation errors as a learning signal⁷ and reflects the dynamic learning processes of positive and negative prediction errors⁸. We made a linear regression of participant's updates as a function of estimation errors. The learning rate (the slope of this linear regression,) indicates how well a person integrates good and bad news into beliefs. The larger the the more participants rely on estimation errors to form a new estimate. BU_{Des} and BU_{Undes} were separately regressed onto PEs, resulting in two standardized regression coefficient: _{Des} and _{Undes}. We then examined OT effects on learning rate to determine how OT influenced learning from desirable and undesirable feedback. To do so, learning

rates () were transformed to Z scores using Fisher's transformation: $\mathbb{Z} = \frac{1}{2} lm(\frac{1+\beta}{1-\beta})$, and while the Transformation to Eardback ANOVAs

subjected to Treatment x Feedback ANOVAs.

Mediation analysis. We performed mediation analyses to examine whether the effects of OT on the optimistic bias (OB, indexed by BU_{Des} minus BU_{Undes}) occurred through the OT effects on confidence update or acceptance of feedback. Similar to our previous studies⁹, a bootstrapping method was used to estimate the mediation effect. Bootstrapping is a nonparametric approach to effect-size estimation and hypothesis testing that is increasingly recommended for many types of analyses, including mediation^{10,11}. Rather than imposing questionable distributional assumptions, bootstrapping generates an empirical approximation of the sampling distribution of a statistic by repeated random resampling from the available data, and uses this distribution to calculate p-values and

Supporting figures

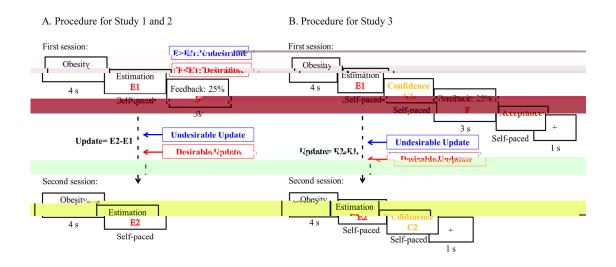

Fig. S1. Illustration of experimental procedures in the current work. In Study 1 (discovery sample) and Study 2 (replication sample), participants completed two sessions of adverse life event estimation (A). In the first session participants were presented with 40 different adverse life events and had to estimate their likelihood of experiencing each life event on a self-paced basis (1st estimation). Participants were then presented with the probability of each event occurring to an average people in a similar socio-cultural environment (feedback). In the second session, participants were presented with the 40 adverse life events in a random order and had to estimate the likelihood of each event again in (2nd estimation). The belief update task in Study 3 was similar to that in Studies 1 and 2, except that, for each event, participants were asked to rate 1) their confidence of the 1st and 2nd Estimate (ranging from 0% to 99%) after their estimation; and 2) their acceptance of the feedback (ranging from 0% to 99%) after the presentation of the feedback probability (B).

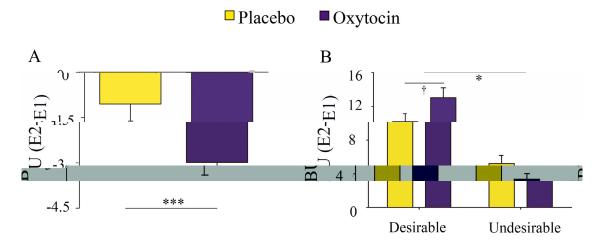

Fig. S2. Distinct OT effects on belief updates in response to desirable and undesirable feedback in Study 3. IN-OT enhanced belief updating upon desirable feedback, but decreased belief updating upon undesirable feedback (*** p<0.001, ** p<0.01, * p<0.05, $\dagger p<0.10$).

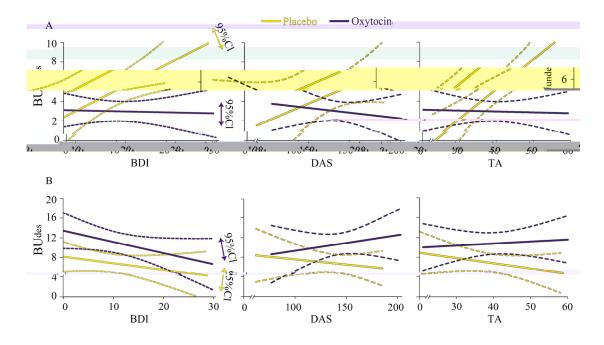

Fig. S3. The results of Treatment x Trait interaction on belief updating in Study 2. Treatment x Trait interaction predicted belief updating upon undesirable feedback (A), but not upon desirable feedback (B) in Study 2. BDI = Beck's depression inventory; DAS= Dysfunctional Attitude Scale; TA = Trait Anxiety.

The moderated hierarchical regression models regressed the moderator (normalized BDI, DAS and TA scores, respectively), independent variable (Treatment), and their interactions onto BU_{Des} and BU_{Undes} , respectively. The analyses of Study 2 showed that the interaction between Treatment and Trait was predictive of BU_{Undes} (BDI: B = -0.41, t (80) = -2.48, p=0.015; DAS: B = -0.27, t (80) = -1.72, p=0.089; TA: B = -0.57, t (80) = -3.74, p<0.001, Fig. S3A; Table S3-5); but not $BU_{DesT1 Tw(A)2.5(: B = -)6.1-.001 613; 2 \text{ showe8.71(80)}}$

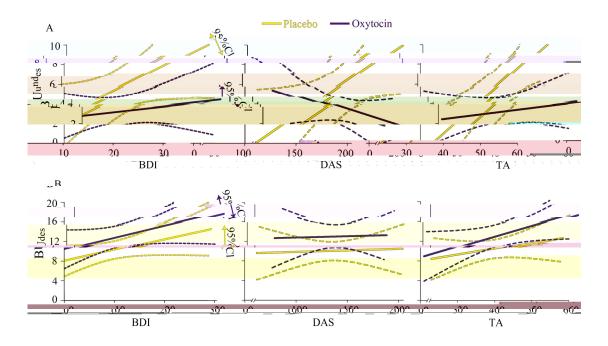

Fig. 4. The results of Treatment x Trait interaction on belief updating in Study 3. Treatment x Trait interaction predicted belief updating upon undesirable feedback (A), but not upon desirable feedback (B) in Study 3. BDI = Beck's depression inventory; DAS= Dysfunctional Attitude Scale; TA = Trait Anxiety.

The moderated hierarchical regression models regressed the moderator (normalized BDI, DAS and TA scores, respectively), independent variable (Treatment), and their interactions onto BU_{Des} and BU_{Undes} , respectively. The analyses of Study 3 showed that the interaction between Treatment and Trait was predictive of BU_{Undes} (BDI: B = -0.17, t (110) =-1.24, p=0.218; DAS: B =-0.30, t (109) = -2.41, p=0.018; TA: B = -0.33, t (110) =-2.33, p=0.022, Fig. S4A; Table S3-5); but not BU_{Des} (BDI: B = 0.01, t (110) = 0.10, p=0.917; DAS: B = -0.001, t (109) = -0.01, p=0.991; TA: B = 0.09, t (110) = 0.58, p=0.562, Fig. S4B; Table S3-5), suggesting that individuals' depression and anxiety traits moderated OT effects on belief updates in response to undesirable feedback. Note: The Treatment x BDI interaction on undesirable updating was reliable in Study 2, and when combined data of Studies 2 and 3. This effect did not reach significant in Study 3 but showed the same pattern as that in Study 2 and combined dataset.

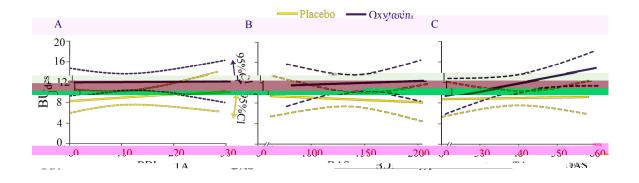

Fig. S5. The results of Treatment x Trait interaction on belief updating upon desirable feedback in data collapsed over Studies 2 and 3. There was no significant Treatment x Trait interaction on belief updating upon desirable feedback (BDI: B =-0.045, t (194) = -0.42, p=0.677, DAS: B = 0.040, t (193) = 0.40, p=0.690; TA: B = 0.123, t (194) = 1.12, p=0.265). BDI = Beck's depression inventory; DAS= Dysfunctional Attitude Scale; TA = Trait Anxiety.

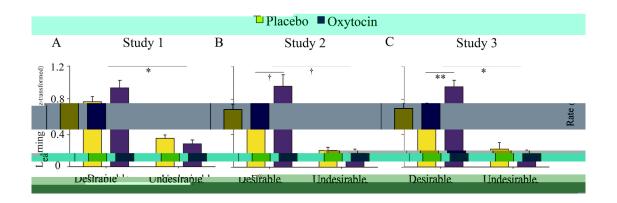

Fig. S6. OT effects on the learning rate for each study. OT, compared to PL, enhanced the strength of the association between estimation error and subsequent update in response to desirable feedback not undesirable feedback in each study.

We found that participants learned to a greater degree from estimation errors in the desirable (than undesirable) trials (Study 1: F(1, 97)=89.252, p<0.001, ²=0.479; Study 2: F(1, 93)=64.647, p<0.001, ²=0.410; Study 3: F(1, 112)=97.512, p<0.001, ²=0.465). Moreover, a significant Treatment x Feedback interaction on the learning rate confirmed that the OT selectively increased participants' learning from prediction error in the desirable but not undesirable trials (Study 1: F(1, 97)=3.989, p=0.049, ²=0.039; Study 2: F(1, 93)=3.842, p=.053, ²=0.040; Study 3: F(1, 112)=5.894, p=0.017, ²=0.050).

 Table S2. Self-reports of adverse life events characteristics

The rating scores of familiarity, negativity, vividness, arousal and prior experience for adverse life events (on 7-point scales: 1=not familiar/negative/vivid/aroused at all; never occurred to me; 7=extremely familiar/negative/vivid/aroused; frequently occurred to me) were compared between OT and PL groups as manipulation check of whether the characteristics of adverse life events were similar between the PL and OT groups. There was no group difference in Studies 2 or 3, for familiarity, negativity, vividness, arousal and prior experience ratings.

 Table S19.
 Memory error (%) for feedback in each study.

The difference between recalled feedback and actually presented feedback was used to indicate memory performance of feedback (Memory error). We compared memory errors respectively for all trials, desirable trials and undesirable trials between the OT and PL groups to see whether OT affected the memory of feedback in each of the three studies. ANCOVA F-test with participants' own estimates as covariate variables has not found consistent significant difference between OT and PL groups in different conditions.
